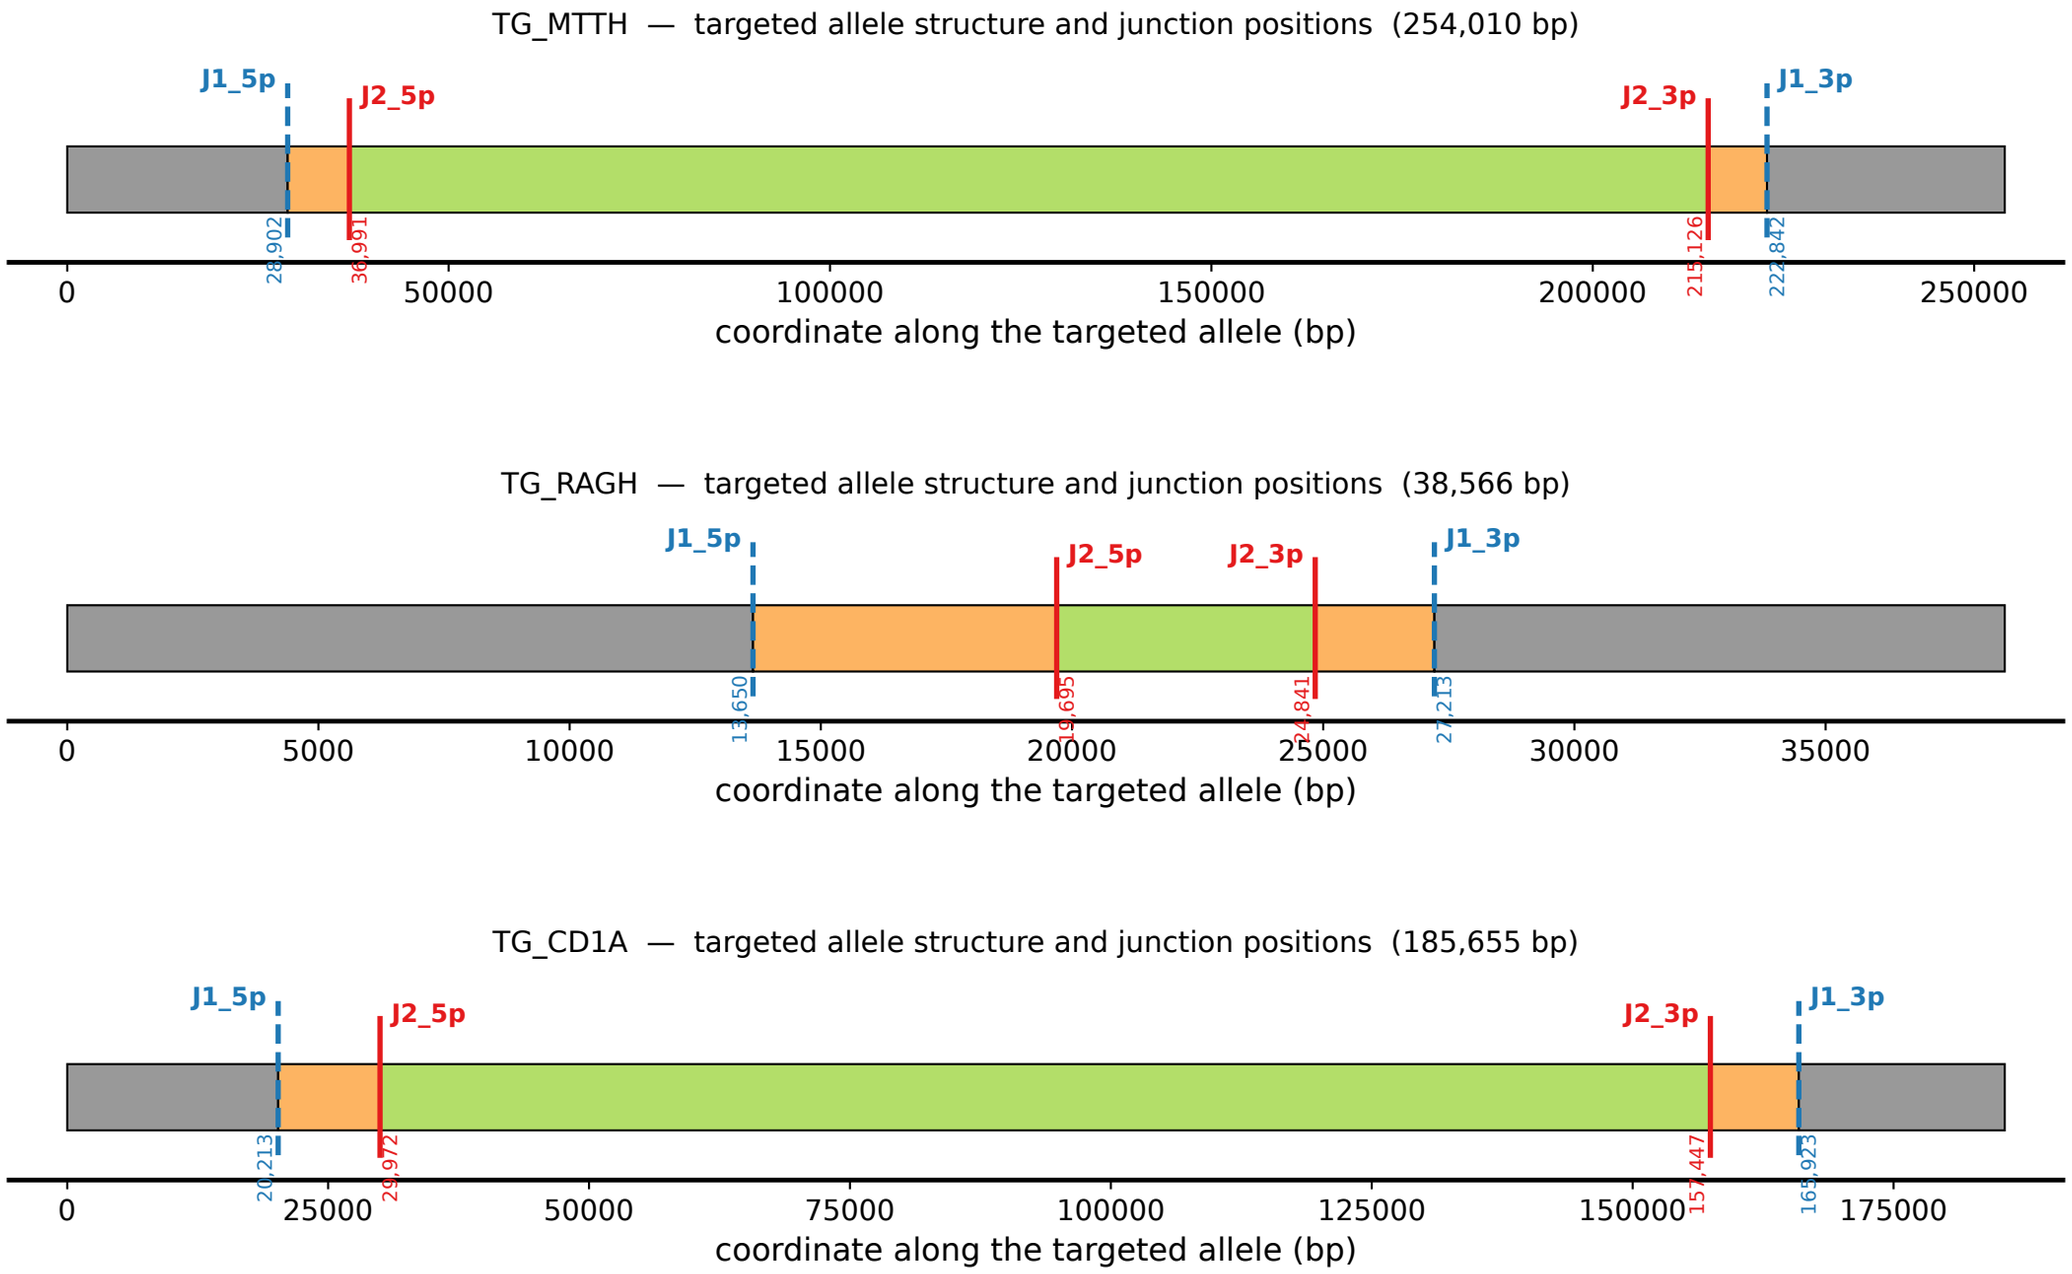
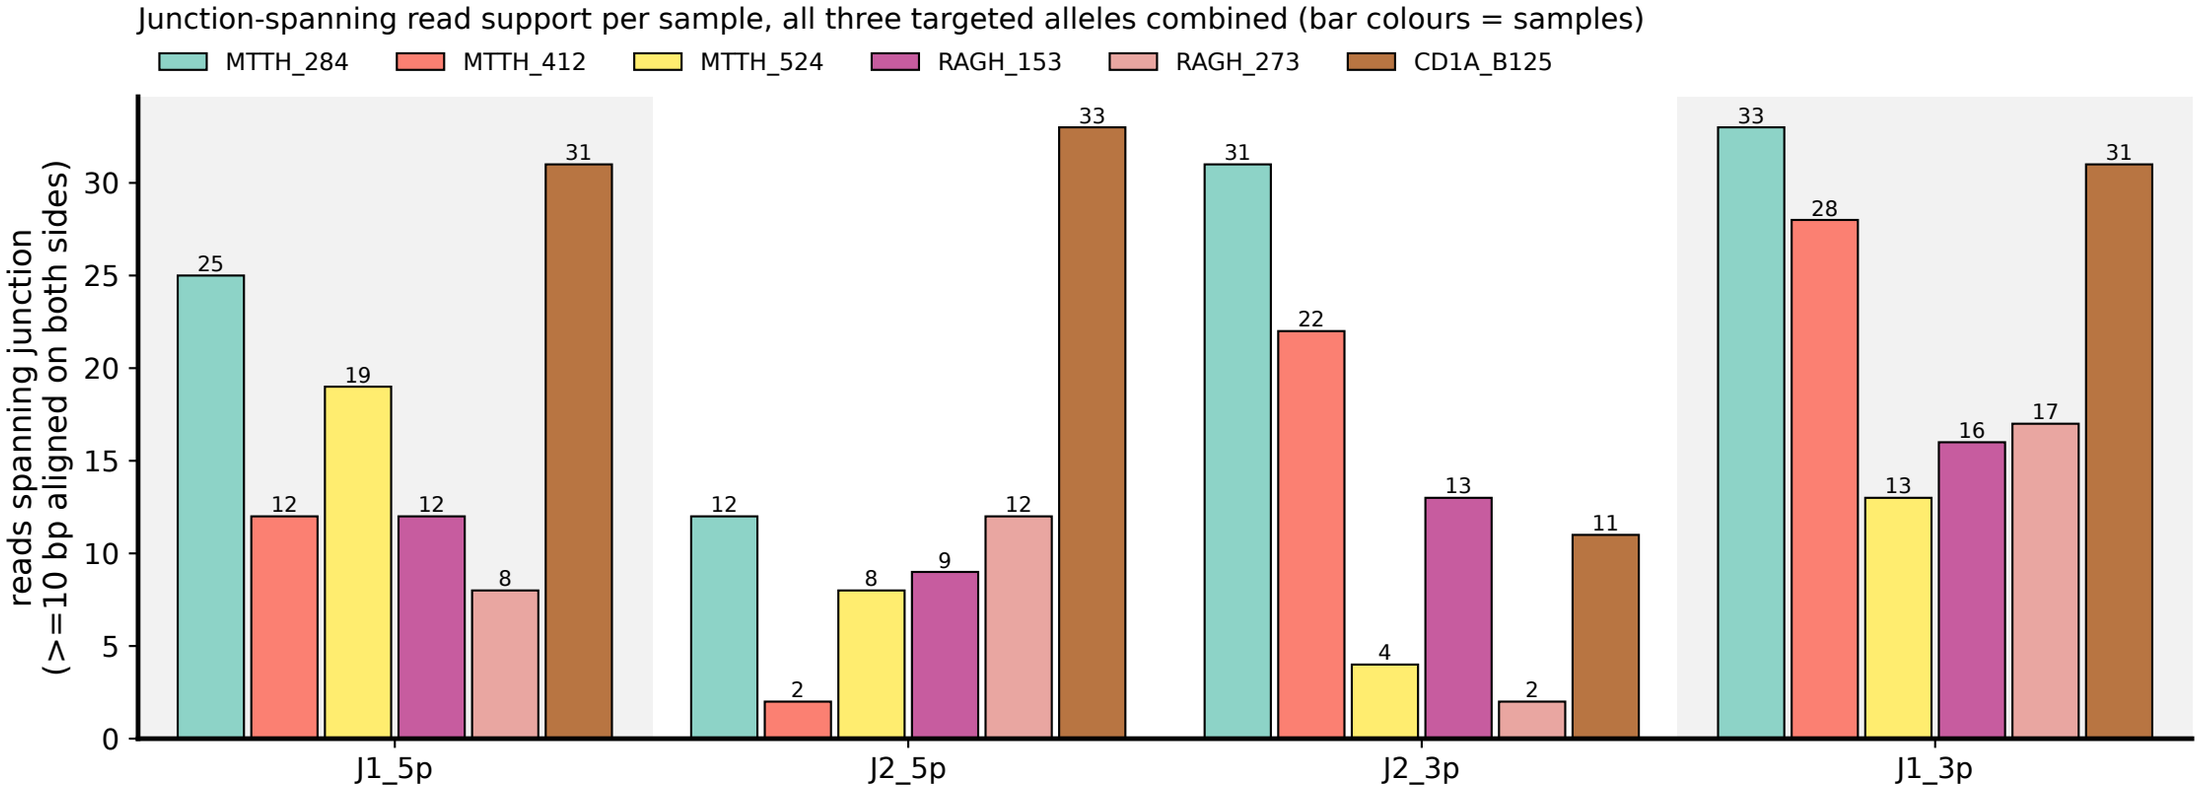
Three targeted alleles side by side — structure (top) and junction-spanning read support (bottom)



Junction-spanning read support per sample, all three targeted alleles combined (bar colours = samples)



Bar colours = samples — a separate colour family from the segment colours in the three panels above, to which they are unrelated. The four groups are junction CLASSES, not one shared coordinate: each sample carries its own targeted allele, so counts are compared within a class, never between loci. The three structure panels are drawn on INDEPENDENT x scales (254,010 / 38,566 / 185,655 bp) and their widths are therefore not comparable.

Shaded groups (J1): the homology arm is identical to the endogenous locus, so these reads cannot be assigned to one or the other — the aligner splits them arbitrarily and reports MAPQ 0. J1 counts are therefore NOT a measure of evidence strength and are not comparable with J2 counts. Only J2 reads (MAPQ 60) uniquely identify the targeted allele.
